Intermediate Water (NPIW); Okhotsk Sea; subarctic North Pacific

1
2 1 Abstract
3

4 2 The Okhotsk Sea is considered the only ventilation source area for North
5
6 3 Pacific Intermediate Water (NPIW), which is widely distributed in the low and middle
7
8 4 latitudes of the North Pacific. Previous studies have confirmed high levels of dissolved
9
10 5 organic carbon (DOC) in NPIW, yet the amounts and the processes driving DOC export
11
12 6 from the Okhotsk Sea are poorly understood. In this study, concentrations of DOC and
13
14 7 dissolved organic nitrogen (DON) were measured in the western Okhotsk Sea during
15
16 8 the summer of 2006, and additional DOC measurements were made during the late
17
18 9 spring of 2010. Results indicate that DOC transport to the intermediate waters
19
20
21 10 (26.7–27.0 σ_θ) occurs through two processes. The first process involves the spread of
22
23
24 11 water discharged from the continental shelf (Dense Shelf Water), which contributes to a
25
26
27 12 DOC and turbidity maxima in the 250–300 m layer of Okhotsk Sea Mode Water
28
29
30 13 (OSMW) located off the eastern Sakhalin coast. The second process involves diapycnal
31
32
33 14 mixing in the Kuril Basin and the Bussol' Strait, where DOC is transported to a depth
34
35
36 15 greater than 800 m. The ratio of DOC:DON in OSMW was significantly higher in the
37
38
39 16 Kuril Basin and Bussol' Strait than off of the Sakhalin coast, which suggests that the
40
41
42 17 transport of terrigenous organic matter from the bottom occurs in the former regions.
43
44 18 DOC and DON efflux from the Okhotsk Sea to the intermediate layer in the North
45
46 19 Pacific water (26.7–27.0 σ_θ) were estimated to be 68–72 Tg C yr⁻¹ and 5.4 Tg N yr⁻¹,
47
48
49 20 respectively, for which the DOC transported by diapycnal mixing accounts for 37%. We
50
51
52 21 conclude that diapycnal mixing in the Kuril Basin and Bussol' Strait regions could play
53
54 22 a significant role in regulating the quality and quantity of DOC exported to the
55
56 23 intermediate water in the North Pacific.

1. Introduction

The Okhotsk Sea is one of the most productive marginal seas due to favorable light conditions and high inputs of macronutrients and iron from the Amur River (Sorokin and Sorokin, 1999; Liu et al., 2009; Nagao et al., 2010). Along with high autochthonous production, the Okhotsk Sea receives a significant amount of dissolved and particulate organic carbon (DOC and POC) from the Amur River. Large amounts of organic matter accumulate on the Siberian Shelf because of the high primary productivity in this area (Saitoh et al., 1996). The matter is then re-suspended by strong tidal mixing (Kowalik and Polyakov, 1998) and transported to the intermediate depths of the northern and northeastern Sakhalin coast via discharge of the shelf water, which is referred to as Dense Shelf Water (DSW) (Kitani, 1973). Nakatsuka et al. (2002, 2004) determined the distributions of DOC and POC in the area of the western Okhotsk Sea north of 53°N in June, 2000. They estimated the terrestrial DOC input from the Amur River at 2.5 Tg C yr⁻¹ from the linear regression intercept of a negative relationship between DOC and salinity in the surface water. They found high DOC concentration and turbidity in the water on the slope of the northeastern Sakhalin coast, which appears related to the discharge of DSW from the shelf. They estimated the inputs of DOC and POC from the shelf to the intermediate layer of the Okhotsk Sea via the discharge of DSW at 13.6 Tg C yr⁻¹ and 0.9 Tg C yr⁻¹, respectively. These inputs were much higher than sinking POC flux (0.2 – 0.5 Tg C yr⁻¹) from the surface to the intermediate layer in the same area. The discharged DSW is further transported to the south along the East Sakhalin Current with mixing to the inflowing North Pacific Water. It eventually flows out to the North Pacific, mainly through the Bussol' Strait (Ohshima et al., 2002, 2010;

48 Katsumata and Yasuda, 2010), which is the largest and deepest (~2200 m) strait between
49 the Kuril Islands.

50 The physical and biogeochemical studies in the Okhotsk Sea have led us to
51 infer that the DOC exported from the Okhotsk Sea contributes substantially to
52 biogeochemical cycling in the intermediate waters of the North Pacific. North Pacific
53 Intermediate Water (NPIW) is comprised of the entire isopycnal layer ($26.7\text{--}26.8\ \sigma_\theta$),
54 which is characterized by a salinity minimum found in the subtropical North Pacific
55 gyre (Talley, 1997). Previous studies have suggested that large amounts of fresh (young)
56 DOC enable NPIW to sustain higher prokaryotic productivity than the surrounding
57 water masses (Nagata et al., 2001; Hansell et al., 2002), and the Okhotsk Sea is
58 considered the main ventilation source area for NPIW (Itoh et al., 2003). However, the
59 amount of and processes involved in DOC export from the Okhotsk Sea are not well
60 understood due to a lack of DOC data from the southern Okhotsk Sea. This is
61 particularly true for the Bussol' Strait, which is known as a site of water mass
62 transformation driven by diapycnal mixing associated with strong tidal flow (Nakamura
63 and Awaji, 2004; Nakamura et al., 2004; Ono et al., 2007). Furthermore, the fate of the
64 DOC transported with the DSW has not been examined in the Sakhalin coast and the
65 Kuril Basin (south end of the Okhotsk Sea). We hypothesize the following: (1) the DOC
66 contained by the discharged DSW is transported to the Kuril Basin, which is then (2)
67 exported down to greater depths in the Bussol' Strait by diapycnal mixing, (3)
68 influencing the quality and quantity of the DOC exported to the intermediate water of
69 the North Pacific. Because the ratio of DOC to dissolved organic nitrogen (DON) is
70 indicative of the source and degradation state of dissolved organic matter (DOM),
71 changes in the quality of DOM occurring with the mixing of water masses may be

determined by comparing the DOC:DON ratios between the water masses (Anderson, 2002; Hopkinson et al., 2002). However, DON values from the Okhotsk Sea are not yet available. The purpose of this study is to evaluate the dynamics of DOM over the mixing processes in the Okhotsk Sea and to estimate their effluxes from the Okhotsk Sea to the intermediate North Pacific.

2. Materials and methods

2.1. Sampling

Seawater samples were taken in the western part of the Okhotsk Sea during the kh06 cruise of the R/V Professor Khromov (Far Eastern Regional Hydrometeorological Research Institute, Russia) conducted in the summer (August 13–September 14) of 2006. Vertical sampling was made at 36 stations using Niskin-X bottles mounted on a CTD-sampling system, and the surface seawater was collected at 25 northern stations by casting a plastic bottle with a spigot (Fig. 1). Sampling bottles were recovered and placed in a tent on the deck. Seawater for DOC and DON analyses was filtered with a pre-combusted Whatman GF/F filter (diameter, 47 mm) by connecting a spigot of the sampling bottle with silicone tubing to an inline plastic filter holder. Filtrates were collected in pre-combusted glass vials with Teflon-lined caps in duplicates and stored in a freezer until analysis. All materials were washed with detergent and 10% HCl before the cruise, and plastic gloves were worn during the processing of samples to avoid contamination. Additional vertical sampling was conducted at 9 stations in the late spring (May 25–June 7) of 2010 during the kh10 cruise of the R/V Professor Khromov to examine temporal changes in DOC distribution.

2.2. Analyses of DOC and DON

2.2.1. Instrument settings

Concentrations of DOC and total dissolved nitrogen (TDN) in the kh06 samples were simultaneously measured using a TOC-V total carbon analyzer equipped with a TNM-1 chemiluminescence detector unit (Shimadzu, Japan). We modified the catalyst packing of a combustion column of TOC-V and increased the flow rate of the compressed air introduced to an O₃ generator of TNM-1 from 0.5 to 0.8 L min⁻¹ to improve the conversion efficiency of nitrogen (N) compounds to an excited NO₂ state. Details of this modification are shown in Figure S1. These modifications gave reliable DOC and DON measurements for the reference seawater (see 2.2.3), but actual conversion efficiency was not evaluated with regards to N-containing compounds such as amino acids. To save maintenance and running time, DOC concentration in the kh10 samples was measured using a TOC-5000A total carbon analyzer (Shimadzu) according to Sohrin and Sempéré (2005).

2.2.2. Routine analysis

During routine analysis, samples were thawed at room temperature, well mixed, and acidified with 2N HCl (1.0% vol/vol). Samples were then high-purity air bubbled through at a flow rate of 150 mL min⁻¹ for 1.5 min within the syringe of TOC-V or at 50 mL min⁻¹ for 10 min within a vial for the analysis on TOC-5000A. An injection of 100 µL of the bubbled sample was introduced to the combustion column, with the analysis generally repeated 3–5 times. To obtain a procedural blank, Milli-Q water was analyzed every four samples, and the average of the pooled peak areas of the Milli-Q water analyses collected over the entire analysis day was then subtracted from the seawater

1
2 120 samples' peak area. NO_3^- accounted for >99% of the dissolved inorganic nitrogen (DIN,
3
4 121 $[\text{DIN}] = [\text{NO}_3^-] + [\text{NO}_2^-] + [\text{NH}_4^+]$) in most (95%) of the samples collected from the
5
6
7 122 intermediate water of the Okhotsk Sea and is expected to be most abundant
8
9 123 N-compound in these samples. Therefore, we chose NO_3^- as a calibration standard
10
11 124 compound of TDN analysis to minimize the analytical errors associated with differences
12
13 125 in conversion efficiency among N-compounds. A calibration curve was obtained by the
14
15 126 analysis of four distinctive concentrations of standard solution. This was prepared every
16
17 127 analysis day by dilution of stock solutions of potassium hydrogen phthalate and
18
19 128 potassium nitrate with freshly supplied Milli-Q water. Only potassium hydrogen
20
21 129 phthalate was included for the analysis with TOC-5000A. The vertical series of samples
22
23
24
25
26 130 were all analyzed on the same day.

27
28
29 131 After the DOC and TDN analyses, the remaining sample waters were kept in
30
31 132 the dark at 0 °C for DIN analysis. Measurements of DIN were performed in duplicated
32
33 133 aliquots using TRAACS 2000 (Bran+Luebbe) according to Hansen and Koroleff (1999)
34
35 134 on the same day or the next day of the DOC and TDN analyses. Concentrations of DON
36
37 135 were obtained by subtracting the average DIN concentration from the average TDN
38
39 136 concentration.
40
41
42

43 137

44 138 2.2.3. Precisions and accuracy

45
46 139 The precision of triplicate or quadruplicate analyses were found to have
47
48 140 average coefficients of variation (CV) of 1.5% (DOC) and 2.8% (TDN) on TOC-V and
49
50 141 TMN-1, and 1.9% (DOC) on TOC-5000A. Precisions of DON concentrations and
51
52 142 DOC:DON ratios were both 12% in average CV and were calculated using the
53
54
55
56
57
58
59
60
61
62
63
64
65

precisions of DOC and TDN. The lower precision of DON and DOC:DON was attributed to the low DON concentration.

DOC and TDN concentrations in the reference seawater (DSR; distributed by D. Hansell Laboratory, University of Miami) were measured every routine analysis day to check the accuracy and consistency of our analysis. Low carbon water (LCW) from Hansell Laboratory was also measured to check the carbon and nitrogen contents in Milli-Q water supplied in our lab. There was no significant difference in DOC measurements between LCW and Milli-Q water over the analyses (average $\pm$ standard deviation of the difference, $-0.3 \pm 1.3 \mu\text{mol C L}^{-1}$, $n = 41$; Student's t -test, $p > 0.05$), and the peak area of TDN analyses was always 0 both for LCW and Milli-Q water. The average peak area of the LCW analysis was subtracted from the DSR measurements to obtain DOC and TDN concentrations in DSR. DOC and TDN concentrations in DSR were $41.8 \pm 1.1 \mu\text{mol C L}^{-1}$ and $33.1 \pm 0.7 \mu\text{mol N L}^{-1}$, respectively ($n = 37$) over the analyses of the kh06 samples, and $43.4 \pm 0.9 \mu\text{mol C L}^{-1}$ ($n = 8$) over the DOC analyses of the kh10 samples. Although the DOC measurements were significantly higher for the analysis of the kh10 samples, the difference was quite small ($\sim 1.5 \mu\text{mol C L}^{-1}$) and the values were well matched with their published values (DOC, 41–44 $\mu\text{mol C L}^{-1}$; TDN, 32.25–33.75 $\mu\text{mol N L}^{-1}$; <http://www.rsmas.miami.edu/groups/biogeochem/CRM.html>). We did not correct the possible systematic differences in the DOC measurements between the cruises.

Data for DON were unattainable for 30 of 430 samples due to machinery issues, such as failure in data storage, occurring during the TDN and DIN analyses. As high TDN measurements were obtained for DSR (34.8 $\mu\text{mol N L}^{-1}$), TDN values were

corrected for the samples collected from Stn. A1 in the North Pacific by multiplying the TDN measurements by the ratio derived from the published TDN value of DSR ($33.0 \mu\text{mol N L}^{-1}$)/TDN measurement of DSR ($34.8 \mu\text{mol N L}^{-1}$).

2.3. Analyses of salinity, turbidity, and chlorophyll *a*

Salinity was measured using an Autosal Salinometer. Turbidity (% transmission) was measured using a laser forescattering type of turbidity meter (Alec Electronics, ATU6-8M) mounted on a CTD-sampling system. Chlorophyll *a* (Chl *a*) concentration was measured according to the non-acidifying protocol of Welschmeyer (1994) after suspended particles were collected on GF/F filters and extracted Chl *a* in N, N-dimethylformamide at -20°C (Suzuki and Ishimaru, 1990).

2.4. Statistics and calculation

Following the successful verification of normality and equal variance by the Shapiro-Wilk test and Levene Median test, respectively, differences between the groups were then tested by the Student's *t*-test or ANOVA. In cases of non-normality, a Mann-Whitney U-test was applied to examine the differences between two groups. For calculation of the inventories of the intermediate waters ($26.7\text{--}27.0 \sigma_{\theta}$), DOC and DON concentrations at the $26.7\sigma_{\theta}$ and $27.0 \sigma_{\theta}$ density levels were obtained by linear interpolation with regards to the stations where a $26.7\text{--}27.0 \sigma_{\theta}$ density range was present. Regarding the stations where water depth was shallower than the depth of $27.0 \sigma_{\theta}$ level, inventory was calculated between the $26.7\sigma_{\theta}$ level and the deepest sampling depth.

3. Results and Discussion

3.1. Distributions of DOC and DON in the surface water

Distinctively low salinity and high DOC and DON concentrations were found from depths of 0–5 m at the stations closest to the Amur River mouth (Stns. G8 and G10) during the kh06 cruise, indicating a DOC and DON supply originating from the Amur River (Fig. S2). To examine the influence of riverine discharge on DOC and DON distributions in the study area, DOC and DON concentrations in the surface water (0–5 m) were plotted as a function of salinity or Chl *a* (Fig. 2). High DOC recorded from a depth of 0 m at Stn.G14 ($299 \mu\text{mol C L}^{-1}$, Fig. S2) was considered an error and omitted from Figure 2 due to suspected contamination by volatile organic carbon during storage. Surface DOC and DON concentrations were negatively correlated to salinity and positively correlated to Chl *a* concentrations (Fig. 2). Changes in salinity explained 99% and 90% of the surface variations for DOC and DON, respectively, whereas variations in Chl *a* explained 44% (DOC) and 72% (DON) of the variation. These results indicate the strong influence of water from the Amur River on the distribution of surface DOC and DON across the study area. This is likely a consequence of high fluvial DOC concentrations found at the mouth of the Amur River ($500\text{--}830 \mu\text{mol C L}^{-1}$; Nagao et al., 2008, Levshina and Karetnikova, 2008). The linear regression equation between the surface DOC and salinity was expressed as $[\text{DOC}] = -(21.3 \pm 0.3) \times \text{salinity} + (756 \pm 10)$ ($r = -0.99$, $n = 68$; Fig. 2). A similar relationship ($[\text{DOC}] = -18.7 \times \text{salinity} + 691$) was reported by Nakatsuka et al. (2004) at a sampling location north of 53°N of our study area, between the 0–5 m layer, in June, 2000.

The molar ratio of the surface DOC:DON significantly decreased from 37.1 to 12.1 with increasing salinity from 16.69 to 33.39 ($r = -0.87$, $n = 57$) (Fig. 2). The

negative correlation appears to reflect the mixing of fluvial DOM (high DOC:DON) with marine DOM (low DOC:DON) rather than any progress in the microbial degradation of DOM. This is due to the fact that the latter process generally raises DOC:DON ratios regardless of the origin of DOM (*i.e.* fluvial versus marine; Wiegner and Seitzinger, 2001; Hopkinson et al., 2002; Lønborg and Søndergaard, 2009). Previous studies have reported higher DOC:DON ratios in terrestrial waters adjacent to forest sites (20.5–103.1) compared to urban and agricultural sites (9.5–19) (Table S1). The observed high DOC:DON ratios (37.1) may reflect the structure of the Amur River watershed, which is dominated by forest and forested wetland of mixed broadleaf and meadows of sedge-reed grass and forbs, with minor contributions from settlement and agricultural land (Yermoshin et al., 2007).

The surface water during kh10 (late spring of 2010) was distinctively characterized from that in kh06 (summer of 2006) by colder water temperature and higher Chl *a* concentrations (Fig. S3). From these results and the monthly satellite observations of the surface Chl *a* distribution (Courtesy of JAXA/TOKAI UNIVERSITY), the study area was considered to be in progress of blooming during kh10 and in a post-bloom condition during kh06. In spite of the different water situations, surface DOC concentrations were similar between the cruises (Figs. 2 and S3).

3.2. Distributions of DOC and DON in DSW

Dense Shelf Water (DSW; $> 26.7 \sigma_\theta$, $< -1^\circ\text{C}$) forms mostly (50–70%) on the Siberian Shelf between January and March when sea ice formation and brine rejection occur (Martin et al., 1998; Gladyshev et al. 2000; Shcherbina et al., 2003), and a

substantial fraction (55%) of the DSW remains on the shelf until May and June (Gladyshev et al., 2000). Temperature in the DSW at Stn. MP2 during kh10 (-1.79 – -1.75 °C), which is the nearest station to the Siberian Shelf, was close to the freezing temperature of the surface seawater with the same salinity (-1.8 °C) (Table 1, Fig. 1). Because pure DSW is defined as water at the freezing temperature (Itoh et al., 2003), the DSW found at Stn. MP2 appears to be less mixed with the surrounding water. DSW was also observed on the shelves of the Sakhalin Bay and the eastern Sakhalin coast (Table 1), where DSW is considered to have been transported from the Siberian Shelf (Gladyshev et al., 2000). There was no significant difference in DOC concentrations in DSW among the shelves (ANOVA, $F = 0.763$, $p > 0.1$), and the average ($60.0 \pm 4.6 \mu\text{mol C L}^{-1}$, $\pm$ standard deviation) was close to the concentrations found in the DSW in the Sakhalin Bay and near the northeastern Sakhalin coast in June, 2000 by Nakatsuka et al. (2004) ($61\text{--}75 \mu\text{mol C L}^{-1}$). Similarly to the finding of Nakatsuka et al. (2004), DOC concentration and turbidity increased concomitantly near the bottom, where turbidity was indicated by the decrease in %transmission (Table 1). This result suggests the re-suspension of accumulated organic matter from the continental shelf during the formation and discharge of DSW (Nakatsuka et al., 2002, 2004). Yoshikawa et al. (2006) reported a very low N^* value of -11 for the DSW on the Siberian Shelf, which is indicative of the progress of denitrification. They demonstrated that a low N^* value is not caused by denitrification in the DSW but by sedimentary denitrification. N^* values ranged between -17.6 and -10.1 in kh06, indicating a supply of dissolved compounds from the sediment to the DSW. DOC:DON ratios in the DSW varied among the stations, with lower ratios at the northern stations (11–15, Stns. G2 and F7) and an overall average of 18 ± 5 ($n = 17$). These DOC:DON ratios are lower than the DOC:DON ratios

(> 37.1) of fluvial organic matter inferred from Figure 2, and a substantial contribution of autochthonous DOM is suggested for the DSW. It should be noted that signatures of terrestrial plant materials were detected in the surface sediment on the Siberian Shelf (Seki et al., 2006), which implies that DSW may contain terrestrial organic carbon when it disturbs the sediment surface during discharge from the shelf.

3.3. Distributions of DOC and DON in Okhotsk Sea Mode Water (OSMW)

3.3.1. Off the Sakhalin coast

DSW is transported southward along the East Sakhalin Current and contributes to the Okhotsk Sea Mode Water (OSMW; $26.7\text{--}27.0\ \sigma_\theta$, $\theta \geq 0\ ^\circ\text{C}$) found off the eastern Sakhalin coast (Yasuda, 1997; Gladyshev et al., 2003). OSMW is identified as a water mass with a low potential vorticity at approximately $26.8\ \sigma_\theta$ level. It is a mixture of DSW, inflowing North Pacific Water, and Soya Warm Current Water (Itoh et al., 2003). The potential temperature in OSMW increases eastward from the eastern Sakhalin coast due to the increasing contribution of warm North Pacific Water to OSMW (Gladyshev et al., 2003). Nakatsuka et al. (2004) reported a decrease in DOC concentration with increasing temperature in the intermediate water ($26.7\text{--}27.0\ \sigma_\theta$ level) off the northeastern Sakhalin coast. OSMW was situated between depths of 74 and 792 m during kh06 and kh10, and concentrations of DOC and DON in the intermediate water were found to decrease with increasing temperature (data not shown). This result implies greater dilution of DOC and DON occurs with increased mixing due to the inflowing North Pacific Water.

Coincident occurrence of DOC and turbidity maxima was observed at approximately $26.8\ \sigma_\theta$ level (250–300 m) in the OSMW off the Sakhalin coast (e.g.,

286 Stns F1 and B1 in kh06), and DOC concentrations were 4–6 $\mu\text{mol C L}^{-1}$ greater than the
287 surrounding depths at the maxima (Fig. 3). At the same density level, minimum N^* peak
288 also occurred (data not shown), and these results imply an inflow of DSW into the
289 OSMW. The occurrence of DOC and turbidity maxima and N^* minima indicates that
290 dissolved matter (DOC and inorganic nutrients) and suspended particles were not
291 diffused but were retained in the OSMW in spite of the water mixing process. This is
292 likely due to the vertical stability maxima located at the upper and lower boundaries of
293 the OSMW (Gladyshev et al., 2000). To examine an effect of lateral DOC export from
294 the Sakhalin shelf on the offshore DOC maxima, DOC distribution is plotted along
295 east-west transects made during kh06 (Fig. 4). DOC concentration in the maxima was
296 higher at the most offshore stations than at the nearest stations along Lines B (49.5°N)
297 and D (54°N), suggesting that these offshore DOC maxima are associated with the
298 DSW discharged from the Siberian Shelf rather than from the Sakhalin shelf.
299 DOC:DON ratios in the OSMW located off the Sakhalin coast (average, 17) were
300 within the ratios of oceanic DOM (Bronk, 2002), suggesting the dominance of
301 autochthonous marine DOM in OSMW. This view is consistent with the enriched $\delta^{13}\text{C}$
302 value of POC in the OSMW located off the northeastern Sakhalin coast (Nakatsuka et
303 al., 2004). DON maxima were negligibly detected at most stations with the exception of
304 Stn. B1 at depths where DOC maxima occurred (Fig. 3). A likely explanation is the low
305 precision of the DON analysis, when assuming the DOC:DON ratio at the DOC
306 maxima represents the average DOC:DON ratio for the OSMW located off the Sakhalin
307 coast (17). In this case, values of 4–6 $\mu\text{mol C L}^{-1}$ of excess DOC forming the maxima
308 would be equivalent to $<0.4 \mu\text{mol N L}^{-1}$ of excess DON from the surrounding depths,

1
2 309 which is lower than the analytical precision of DON in the intermediate water ($0.5 \mu\text{mol}$
3
4 310 N L^{-1}).
5
6

7 311
8
9 312 3.3.2. Kuril Basin and Bussol' Strait
10

11 313 DOC maxima were not obvious in or near the Kuril Basin (Stn. A6 in kh06 and
12
13 314 Stn. A4 in kh06 and kh10) or at some stations in the Bussol' Strait (Stns. Bussol-9 and
14
15 315 Urup-E in kh06 and Stn. BW1 in kh10) (Fig. 3). The lower boundary of OSMW (27.0
16
17 316 σ_θ) was located deeper in the Kuril Basin and Bussol' Strait (Fig. 3), suggesting the
18
19 317 dispersion of DOC within the expanded OSMW. In fact, the downward replacement of
20
21 318 the $26.8 \sigma_\theta$ level was observed at a shallow site in the Bussol' Strait during kh06 (Itoh et
22
23 319 al., 2010). The hypothesis attributing the downward transport of DOC in the Kuril Basin
24
25 320 and the Bussol' Strait was investigated by plotting cross-sections of the lines connecting
26
27 321 the stations located furthest offshore (Fig. 5). An isoline of $27.0 \sigma_\theta$ increased in depth
28
29 322 between the location in the Kuril Basin (Stn. A4) and the Bussol' Strait (Stns. Bussol-9
30
31 323 and BW1), reaching a maximum depth of ca. 600 m (kh10) or 800 m (kh06) in the Kuril
32
33 324 Basin. An area of high DOC concentrations ($\geq 47 \mu\text{mol C L}^{-1}$) presumably follows the
34
35 325 isoline of $27.0 \sigma_\theta$, penetrating down to 500–800 m in the Kuril Basin and the Bussol'
36
37 326 Strait. This depth is greater than the extent of DOC transported via the formation of
38
39 327 OSMW by isopycnal mixing of the DSW with the inflowing waters, which had been
40
41 328 inferred from DOC maxima recorded off the eastern Sakhalin coast ($< 300 \text{ m}$; Fig. 3).
42
43 329 Surface DOC concentrations were lower in the Bussol' Strait than off the eastern
44
45 330 Sakhalin coast, which is presumably related to the low primary productivity and dilution
46
47

with upwelling deeper water inferred from low Chl *a* concentrations and temperature in this region, respectively (Fig. S3).

Near the eastern slope of the Bussol' Strait (Stn. Bussol-13) during kh06, the DOC maximum was observed at 400 m ($26.78 \sigma_\theta$). Here, turbidity was also found to be relatively higher than OSMW measurements collected at the other stations (Fig. 3). This DOC maximum appears to be largely due to contributions of DOC exported from the lower layer rather than DOC from the upper layer, as the DOC:DON ratio in OSMW (19 ± 4) was comparable to the ratio calculated for the lower layer (20) but was significantly higher than the DOC:DON ratio in the upper layer (15 ± 4) at Stn. Bussol-13 (Student's *t*-test, $p < 0.05$) (data not shown). Indeed, DOC:DON ratios in OSMW were significantly higher in the Kuril Basin and the Bussol' Strait (median, 19) than off the Sakhalin coast (median, 16) (Mann-Whitney U-test, $p < 0.01$), although the ratios were comparable between these two regions with regard to the upper and lower layers (Mann-Whitney U-test, $p > 0.1$) (Fig. 6). These results suggest that diapycnal mixing did not disturb the sediment surface in the sampling period, but it influenced the DOM composition of OSMW when it occurred near the bottom the last time. We infer that vertical mixing temporally occurring close to the bottom of the Bussol' Strait, as shown in a numerical experiment (Nakamura and Awaji, 2004), facilitates the temporal release of organic matter from the disturbed sediment. This occurs via the re-suspension and flushing out of DOM-rich pore-water and then transports DOC to the $26.8 \sigma_\theta$ level by production of low potential vorticity water at around this level (Ono et al., 2007). This process can increase DOC:DON ratios in OSMW, if the terrigenous organic matter was accumulated on the bottom. Seki et al. (2006) detected signatures of terrestrial plant materials from the surface sediment and the sediment traps deployed at depths equal to

or below the OSMW near the Kuril Basin. Higher contributions of lignin-related materials found in both the DOC and POC fractions in the lower NPIW (750 m), when compared to other depths in the subtropical North Pacific (Hernes and Benner, 2002), might be associated with the mixing processes occurring in the Bussol' Strait, with subsequent export into the North Pacific. The DOC and turbidity values detected in the OSMW were relatively low at the other sampling sites in the Bussol' Strait (Fig. 3). Spatial differences in the vertical profiles of DOC are presumably related to regional and temporal differences in the strength of vertical mixing around the Kuril Islands, which depends on the local topography and direction of tidal current (Itoh et al., 2010).

3.4. DOC fluxes in the intermediate waters

We attempted to evaluate DOC and DON fluxes in the intermediate waters of the Okhotsk Sea and the North Pacific, with the results presented in Figure 7. DOC and DON fluxes related to the DSW discharge were obtained by multiplying the average of the DOC and DON concentrations in the DSW (Table 1) by the annual average volume rate of the DSW discharge. The annual average rate of the DSW discharge was obtained from the annual volume production of the DSW, assuming a discharge time of 1 year, because the DSW is considered to be replaced every winter (Gladyshev et al., 2000). Annual production of the DSW was calculated from its proportional relationship to the maximum sea ice volume (Nihashi et al., 2009). This relation was established for the Siberian Shelf, and we applied the relationship to the entire shelf region. The maximum sea ice volume was obtained from the averaged sea ice area observed in February–March of 2006 (Nakanowatari et al., 2010), or the area predicted for winter of 2010 (http://www.od.lawtem.hokudai.ac.jp/~ohshima/social/2011/sie_prediction.html),

assuming the ice thickness of 1 m (Nihashi et al., 2009). The annual average rate of
 DSW discharge was estimated at 0.42 and 0.65 Sv ($1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$) in 2006 and 2010,
 respectively, and the values are similar to the estimates in previous studies (0.24–0.6 Sv;
 Gladyshev et al., 2003). The DOC flux related to the DSW discharge was estimated at
 9.8 Tg C yr^{-1} (2006) and 14 Tg C yr^{-1} (2010), averaging 12 Tg C yr^{-1} , and the
 corresponding DON was 0.67 Tg N yr^{-1} (2006). Our estimated DOC flux was
 comparable to the estimate by Nakatsuka et al. (2004) (13.6 Tg C yr^{-1}). This was based
 on a previous estimate of the rate of the DSW discharge and the regression result
 between DOC and temperature in the intermediate water in the northeastern Sakhalin
 coast, with the assumed temperature of -1.5°C for the DSW flowing out from the shelf.
 The estimated DOC and DON fluxes may contain an error introduced by representing
 the concentration in the discharged DSW by the results obtained in June and September
 because the rate of DSW discharge decreases substantially after May (Gladyshev et al.,
 2003; Shcherbina et al., 2003). Satellite Chl *a* observations (Courtesy of JAXA/TOKAI
 UNIVERSITY) suggest that extensive primary production occurs on the Siberian Shelf
 in March, which corresponds with the period after the end of DSW formation
 (Gladyshev et al., 2000). Therefore, the DOM produced under a bloom condition is
 considered to be an unlikely contributor to the DSW, excepting the supply via
 dissolution of the settled particles.

DOC and DON fluxes into the North Pacific were calculated by multiplying
 the DOC and DON concentrations in the Bussol' Strait by the volume of the outflow
 transported. We referred to the volume transport values obtained at the $0.1 \sigma_\theta$ interval
 from direct observation during one tidal cycle in September, 2001 by Katsumata et al.
 (2004). Regarding the $26.7\text{--}27.0 \sigma_\theta$ level, the DOC efflux into the North Pacific was

evaluated at 68 Tg C yr⁻¹ (Stn. Bussol-9 in kh06), 72 Tg C yr⁻¹ (Stn. Bussol-13 in kh06), and 69 Tg C yr⁻¹ (Stn. BW1 in kh10), averaging 69 ± 2 Tg C yr⁻¹. Total DOC efflux is evaluated at 135 Tg C yr⁻¹ with regards to the whole density level (26.0–27.4 σ_θ), where the positive volume flux was observed by Katsumata et al. (2004). The DON efflux on the 26.7–27.0 σ_θ level is 5.3 Tg N yr⁻¹ (Stn. Bussol-9 in kh06) and 5.5 Tg N yr⁻¹ (Stn. Bussol-13), averaging 5.4 Tg N yr⁻¹, while the total DON efflux is 11 Tg N yr⁻¹ with regards to the 26.0–27.4 σ_θ level. These estimates may contain errors introduced by the large seasonal variations in the amount of volume transport associated with the outflow (Katsumata and Yasuda, 2010).

DOC and DON added to OSMW via diapycnal mixing in the Kuril Basin-Bussol' Strait region can be calculated from the difference in the DOC (DON) inventory of OSMW between the eastern Sakhalin coast and the Kuril Basin-Bussol' Strait region. DOC inventory was 180 ± 20 g C m⁻² ($n = 10$, n is a number of stations where whole density level of OSMW existed) off the eastern Sakhalin during kh06 and kh10. By subtracting this value from the DOC inventory at the stations in the Bussol' Strait, the depth-weighted average concentration of the added DOC via diapycnal mixing was estimated at 15.4–21.8 $\mu\text{mol C L}^{-1}$. By multiplying the volume transport for the 26.7–27.0 σ_θ level (3.58 Sv; Katsumata et al., 2004), the DOC flux added to OSMW via diapycnal mixing in the Kuril Basin-Bussol' Strait region was estimated at 21–30 Tg C yr⁻¹ (25 ± 4 Tg C yr⁻¹, $n = 3$; n is a number of stations at Bussol' Strait excluding Stn. Urup-E in kh06, where DOC was not measured at 27.0 σ_θ level). In the same manner, the corresponding DON flux was estimated at 1.4 Tg N yr⁻¹. From these calculations and the assumption of conservative transport of the DOC and DON added to OSMW,

the DOC flux from off the eastern Sakhalin coast to the Kuril Basin-Bussol' Strait region would be 41–48 Tg C yr⁻¹ (44 ± 3 Tg C yr⁻¹), and the DOC flux added to OSMW off the eastern Sakhalin coast was estimated at 32 Tg C yr⁻¹ (32–33 Tg C yr⁻¹) from the difference in DOC fluxes toward and away from the region. The corresponding DON fluxes are 4.0 Tg N yr⁻¹ and 3.3 Tg N yr⁻¹, respectively.

We attempt to obtain a rough estimate of the residence time of OSMW from the DOC fluxes that were made with the assumption of conservative DOC transport. If our estimated residence time is comparable to the values in literature, the assumption of a conservative DOC transport would be verified. By using the volume of OSMW in the Okhotsk Sea (2.85×10^{14} m³; Itoh et al., 2003) and the Kuril Basin (9.5×10^{13} m³; Galdyshev et al., 2003), the depth-weighted average DOC concentrations off the Sakhalin and the Kuril Basin-Bussol' Strait region, and the DOC fluxes away from these regions, DOC pool size and residence time of OSMW were estimated at 117 Tg C and 2.7 yr (off the Sakhalin) and 58 Tg C and 0.9 yr (Kuril Basin-Bussol' Strait), respectively. These residence times are within a range of the estimates in previous studies; 1.4–7 years for the Okhotsk Sea (Wong et al., 1998; Itoh et al., 2003) and 290 days–2 years for the Kuril Basin (Yasuda, 1997; Gladyshev et al., 2003; Ohshima et al., 2010). A sum of the residence time of the DSW (~1 year) and OSMW (3.6 year) reveals that DOC produced in the surface water of the shelf region would reach the intermediate North Pacific after ~5 years. Although a part of semi-labile DOC (assumed turnover of months to years; Hansell et al., 2012) might reach the North Pacific, its bioavailability remains uncertain. High prokaryotic productivity found in NPIW (Nagata et al., 2001) might be partly supported by the DOC added via diapycnal mixing in the Bussol' Strait. Previous studies have revealed that transport of the upper layer water down to below the

OSMW occurs in the Bussol' Strait by diapycnal mixing (Yamamoto-Kawai et al., 2004; Ono et al., 2007), which is consistent with the low surface water temperature in this region (Fig. S2). Because current near the surface is about 10-fold faster than OSMW with turnover time of 0.5 year (Ohshima et al., 2002), diapycnal mixing in the Bussol' Strait can transport two distinct, relatively fresh DOM pools into OSMW: laterally transported DOM from the northern surface water by the surface current and the autochthonous DOM produced in the surface water of the Bussol' Strait. These are possible carbon sources that support high prokaryotic productivity in NPIW.

As a result, production of OSMW off the eastern Sakhalin coast and in the Kuril Basin-Bussol' Strait region contributes more to the efflux of DOM into the North Pacific (DOC, 46% and 37%; DON, 61% and 27%, respectively) than does the discharge of DSW (DOC, 17%; DON, 12%) (Fig. 7). Our results suggest that production of OSMW via diapycal mixing in the Kuril Basin-Bussol' Strait region is an important process for DOM export in terms of quantity and quality.

3.5. North Pacific

In the North Pacific, DOC concentrations were measured near the Bussol' Strait (Stn. A1) during kh06 and kh10 and the Kruzenshtern Strait (Stn. BNK2) during kh10. The Kruzenshtern Strait is a passage through which the greatest amount of the North Pacific Water inflows to the Okhotsk Sea (Katsumata and Yasuda, 2010). DOC concentration largely differed in the intermediate water (26.7–27.0 σ_θ) between kh06 and kh10, with the highest concentration of 63.6 $\mu\text{mol C L}^{-1}$ (Stn. A1 in kh06) and 50.3 $\mu\text{mol C L}^{-1}$ (Stn. A1 in kh10) (Fig. 3). The highest DOC concentrations, found at 26.8 σ_θ , were comparable between Stns. A1 and Bussol-13 during kh06, suggesting that the

intensive transport of water with high DOC concentrations occurs at 26.8 σ_θ , and previous studies have reported the strongest outflow occurring at around 26.8 σ_θ (Wong et al., 1998; Katsumata et al., 2004; Katsumata and Yasuda, 2010). By applying a water mass analysis of Ono et al. (2007), the 26.8–27.2 σ_θ level at Stn. A1 was found within the values of the waters in the Kuril Basin and the East Kamchatka Current during kh06, while it was similar to the property of the water in the East Kamchatka Current (East Kamchatka Current Water) during kh10 (Fig. 8). This result suggests that the intermediate water at Stn. A1 was more influenced by the East Kamchatka Current Water at the sampling period during kh10. The East Kamchatka Current is a part of the cyclonic circulation of the Western Subarctic Gyre and flows southward from the Bering Sea. A strong flow (8 Sv) is estimated at the 26.7–27.0 σ_θ level of the East Kamchatka Current Water near Stn. A1 (Iwao et al., 2003), which is equal to or larger than a volume transport of the Okhotsk Sea outflow through the Bussol' Strait [4.3–8.8 Sv; Nakamura and Awaji (2004) and references therein]. The East Kamchatka Current Water and the outflowing Okhotsk Sea water produce the Upstream Oyashio water in the south of the southern Kuril Islands by isopycnal mixing, which is an important source of NPIW (Yasuda et al., 1997). The observed higher DOC concentration, associated with the outflowing Okhotsk Sea, suggests that the Okhotsk Sea is a more important source for DOC in NPIW than the Bering Sea. For a better understanding of DOM transport to NPIW, future studies may address the mixing of the outflowing Okhotsk Sea water and East Kamchatka Water in the vicinity of the Kuril Islands.

4. Conclusion

Distributions of DOC and DON in the western Okhotsk Sea were determined during the summer of 2006 and those of DOC during the late spring of 2010. The surface distributions of DOC and DON were strongly influenced by the Amur River water, with higher DOC and DON concentrations and DOC:DON ratios in lower salinity regions. Maxima of DOC and turbidity were coincident in the OSMW located off the eastern Sakhalin coast, suggesting a DOC transport associated with the discharged DSW presumably from the Siberian Shelf. DOC and turbidity maxima were not obvious and the thickness of OSMW increased in the Kuril Basin and the Bussol' Strait, where production of OSMW related to vigorous diapycnal mixing has been inferred in previous studies. DOC:DON ratios in OSMW were slightly high in the Kuril Basin and the Bussol' Strait, and may be related to the export of terrigenous organic carbon from bottom sediments via diapycnal mixing. Diapycnal mixing also appeared to transport fresh DOM from the surface to OSMW. Effluxes of DOC and DON to the intermediate North Pacific, which includes the NIPW density level, were 135 Tg C yr^{-1} and 11 Tg N yr^{-1} , respectively, on the $26.0\text{--}27.4 \sigma_\theta$ density level [where a positive volume flux was observed by Katsumata et al. (2004)]; and 69 Tg C yr^{-1} and 5.4 Tg N yr^{-1} on the OSMW $26.7\text{--}27.0 \sigma_\theta$ density level. Fluxes associated with the OSMW production were comprised by two processes: isopycnal mixing off the eastern Sakhalin coast, and diapycnal mixing in the Kuril Basin and the Bussol' Strait. Fluxes associated with the OSMW production contributed more to the effluxes into the intermediate North Pacific than the fluxes related to the DSW discharge, indicating the importance of water mass transformation in the open Okhotsk Sea for DOM export to NPIW.

665 Yoshikawa, C., Nakatsuka, T., & Wakatsuchi, M. (2006). Distribution of N* in the Sea
666 of Okhotsk and its use as a biogeochemical tracer of the Okhotsk Sea Intermediate
667 Water formation process. Journal of Marine Systems, 63, 49-62.

668 Figure captions

669 Figure 1. Schematic showing the study area where the kh06 (August–September, 2006;
670 large circles) and kh10 (May–June, 2010; black circles) cruises were conducted.
671 Measurements taken for the vertically collected samples are shown for each of the DOC
672 collection stations.

673

674 Figure 2. Plots comparing salinity and chlorophyll *a* (Chl *a*) concentration with DOC
675 and DON concentrations, and with DOC:DON ratios, for the surface waters
676 measurements during the kh06 cruise and the corresponding relationships with DOC in
677 the kh10 cruise. Lines were fitted by linear regression, with the regression results given
678 in the plots.

679

680 Figure 3. Vertical profile plots showing concentrations of DOC and DON, and %
681 transmission values measured in the upper 2000 m of the water column, at
682 representative stations located in the distinctive regions. Station locations are shown in
683 Fig. 1. Water depth is shown in parenthesis for values exceeding 2000 m. Shaded areas
684 indicate the intermediate waters with densities of 26.7–27.0 σ_θ . Error bars indicate the
685 standard deviation associated with the analyses. Note that smaller % transmission
686 values correspond to higher turbidity levels.

687

688 Figure 4. Vertical section plots illustrating DOC concentrations along Lines B (49.5°N),
689 C (52.25°N) and D (54°N) during the kh06 cruise. Locations are shown in Fig. 1. The
690 broken lines indicate isopycnals of 26.7 σ_θ and 27.0 σ_θ . Dots are representative of the
691 sampling depths of DOC.

692

693 Figure 5. Vertical section plots illustrating DOC concentrations along north-south
694 transects during the kh06 (Line kh06) and kh10 (Line kh10) cruises. Locations are
695 shown in Fig. 1. The broken lines indicate isopycnals of $26.7 \sigma_\theta$ and $27.0 \sigma_\theta$. Dots are
696 representative of the sampling depths of DOC.

697

698 Figure 6. Box plots of DOC:DON ratios in the distinctive layers off the Sakhalin coast
699 and in the Kuril Basin-Bussol' Strait region. Upper (lower) ends of boxes and error bars
700 show 75% (25%) and 90% (10%) confidence intervals (CI), and upper (lower) dots
701 show 95% (5%) CI, respectively. Solid lines in boxes show medians. Asterisks denote
702 the significantly different ratios between the regions. DOC:DON ratios in 0–5 m depths
703 were excluded because of the influence of the Amur River water and the ratios at Stn.
704 A6 were also excluded because of its location on the slope of the Kuril Basin. Number
705 of data is shown in parenthesis. Note that 5%, 10%, 90% and 95% CI are not computed
706 with regards to the samples with $n < 8$.

707

708 Figure 7. DOC and DON fluxes in the intermediate waters ($26.7\text{--}27.0 \sigma_\theta$) of the western
709 Okhotsk Sea and the North Pacific. Percentage values in parentheses represent the
710 contributions of the fluxes to the efflux into the North Pacific. Periods in boxes are
711 residence time of the intermediate waters that are assumed (Shelf) or calculated from
712 the distribution of DOC (off Sakhalin and Kuril Basin-Bussol' Strait region). Note that
713 total effluxes of DOC and DON to the intermediate North Pacific is 135 Tg C yr^{-1} and
714 11 Tg N yr^{-1} , respectively, with regards to the whole density level ($26.0\text{--}27.4 \sigma_\theta$) where
715 the positive volume flux was observed by Katsumata et al. (2004).

716

717 Figure 8. Comparison of potential temperature (θ)-salinity diagrams between the North
718 Pacific (Stns. A1 and BNK2, circle) and the Kuril Basin (Stn. 4, triangle) during the
719 kh06 (closed symbols) and kh10 (open symbols) cruises, with those of the East
720 Kamchatka Current Water (solid line) and the OSMW in the Kuril Basin (Kuril Basin
721 Water, broken line). The diagrams associated with the East Kamchatka Current Water
722 and the Kuril Basin Waters are shown with potential temperature standard deviations at
723 $0.1 \sigma_\theta$ intervals, with reference to Ono et al. (2007).

Table 1

Table 1 . Physical and biogeochemical parameters and DOC and DON concentrations and their ratios in the DSW found in the shelf region.

Shelf (period)	Station	Water depth (m)	Depth (m)	θ (°C)	Salinity	σ _θ	Transmission (%)	N* (μmol N L ⁻¹)	DOC (μmol C L ⁻¹)	DON (μmol N L ⁻¹)	DOC/DON (mol:mol)

Figure captions of supplementary material

Figure S1. Schematic of a catalyst packing in a combustion column located in a TOC-V analyzer used for DOC and TDN analyses. All materials were the original supplies for TOC-V, other than Cr_2O_3 (Elemental Microanalysis Ltd, UK), quartz wool (Tosoh SGM, Japan), and squared platinum mesh (Sumika Chemical Analysis Service Ltd, Japan). The grain size of Cr_2O_3 was selected according to Ogawa et al. (1999; Deep Sea Research I, 46, 1809-1826). It should be noted that the platinum ST-type catalyst (Shimadzu) placed on the top of the combustion column seems important for sustaining a sufficient oxidation efficiency of DOC, but is easily reduced to a powder form by repeated injections, resulting in decreasing measurement readings. To overcome this problem, the top ST catalyst was changed every 2–3 days of analysis. We also altered the flow rate of the compressed air introduced to an O_3 generator of TNM-1 from 0.5 to 0.8 L min^{-1} . Preliminary measurements of TDN in deep seawater (1000 m depth) from the Suruga Bay, central Japan, were conducted according to the manufacturer's protocol, but the measurement readings were lower (average, 36.2 $\mu\text{mol N L}^{-1}$) than the values obtained from colorimetric measurements of dissolved inorganic nitrogen (DIN, $[\text{DIN}] = [\text{NO}_3^-] + [\text{NO}_2^-] + [\text{NH}_4^+]$; 40.2 $\mu\text{mol N L}^{-1}$). The modification to the catalyst packing improved the TDN measurements for the Suruga Bay deep seawater to 40.1 $\mu\text{mol N L}^{-1}$, and the increase in airflow rate further improved the measurements to 42.9 $\mu\text{mol N L}^{-1}$. An increase in airflow rate alone was not found to improve the measurements (36.9 $\mu\text{mol N L}^{-1}$). We consider that these modifications have improved conversion efficiency of N-compounds sufficiently, since our TDN measurements for the reference seawater (Deep Seawater Reference, DSR; distributed by D. Hansell Laboratory, University of Miami) were comparable to its published value (see 2.2.3). However, analyses of standard N-compounds such as amino acids are necessary for more thorough evaluation of our improved method.
